Forecasting Protests by Detecting Future Time Mentions in News and Social Media

Sathappan Muthiah

(ABSTRACT)

Civil unrest (protests, strikes, and "occupy" events) is a common occurrence in both democracies and authoritarian regimes. The study of civil unrest is a key topic for political scientists as it helps capture an important mechanism by which citizenry express themselves. In countries where civil unrest is lawful, qualitative analysis has revealed that more than 75% of the protests are planned, organized, and/or announced in advance; therefore detecting future time mentions in relevant news and social media is a simple way to develop a protest forecasting system. We develop such a system in this paper, using a combination of key phrase learning to identify what to look for, probabilistic soft logic to reason about location occurrences in extracted results, and time normalization to resolve future tense mentions. We illustrate the application of our system to 10 countries in Latin America, viz. Argentina, Brazil, Chile, Colombia, Ecuador, El Salvador, Mexico, Paraguay, Uruguay, and Venezuela. Results demonstrate our successes in capturing significant societal unrest in these countries with an average lead time of 4.08 days. We also study the selective superiorities of news media versus social media (Twitter, Facebook) to identify relevant tradeoffs.

Dedication

To my wonderful Mom, Dad and Brothers

Acknowledgments

First and foremost I would like to thank my advisor Dr.Naren Ramakrishnan. He was not only instrumental in kindling my interest in machine learning and data mining but is also my mentor in many ways.
I would like to thank my fellow graduate students Shahriar Hossain, Rupinder Paul Khandpur, Aravindan Mahendiran, Wei Wang, Fang jin, Patrick Butler, Prithwish Chakraborty, Parang Saraf and Saurav Ghosh. Their help and support were invaluable throughout my graduate studies.

I also like to thank all our collaborators at CACI inc., Graham Katz, Andrew Doyle, Ilya Zavorin and Chris Ackerman for their help with Software Testing and Integration.

Finally I would also like to thank my roommates Rajesh Subbiah, Arvinth Chanthar Rathinama Saran Kumar and Chao Yang for making my stay at Blacksburg a memorable one

Chapter 1

Introduction

Civil unrest (protests, strikes, and "occupy" events) is a common happening in both democracies and authoritarian regimes. Although we typically associate civil unrest with disruptions and instability, for a social scientist civil unrest reflects the democratic process by which citizenry communicate their views and preferences to those in authority. The advent of social media has afforded citizenry new mechanisms for organization and mobilization, and online news sources and social networking sites like Facebook and Twitter can provide a window into civil unrest happenings in a particular country.

Our basic hypothesis is that protests that are larger will be more disruptive and communicate support for its cause better than smaller protests. Mobilizing large numbers of people is more likely to occur if a protest is organized and the time and place announced in advance. Because protest is costly and more likely to succeed if it is large, we should expect planned, rather than spontaneous, protests to be the norm. Indeed, in a sample of 288 events from our study selected for qualitative review of their antecedents (more details later), for 225 we located communications regarding the upcoming occurrence of the event in media, and only 49 could be classified as spontaneous (we could not determine whether communications had or had not occurred in the remaining 14 cases).

We sought to develop a computational protest forecasting system by identifying and mining mentions of future planned events in (news and social) media. Why is this problem difficult? Consider the example article shown in

Figure 1.1: An example article describing plans for a future protest (Venezuela, June 11, 2014).

Fig. 1.1, covered in greater detail in Fig. 5.3. Written in Spanish and published in Venezuela, it describes plans to protest on 'Sunday' and mentions at least five different locations – of which at least two are ambiguous and can either be in Colombia, Cuba or Venezuela. Significant reasoning is required to discern the correct protest location and to identify the intended date from the vague reference of 'Sunday.' Once the location and time of the future protest are inferred, a suitably generated alert has applications to a wide range of governmental and civil activity, from the issuance of travel warnings to rapid emergency response capabilities.

Our detection approach combines shallow linguistic analysis to identify a corpus of relevant documents (articles, tweets) which are then subject to targeted deep semantic analysis. Despite its simplicity, we are able to detect indicators of event planning with surprisingly high accuracy. Our contributions are:

1. We present a protest forecasting system that couples three key technical ideas: key phrase learning to identify what to look for, probabilistic soft

logic to reason about location occurrences in extracted results, and date normalization to resolve future tense mentions. We demonstrate how the integration of these ideas achieves objectives in precision, recall, and quality (accuracy).

2. We illustrate the application of our system to 10 countries in Latin America, viz. Argentina, Brazil, Chile, Colombia, Ecuador, El Salvador, Mexico, Paraguay, Uruguay, and Venezuela. We conduct ablation studies to identify the relative contributions of news media (news + blogs) versus social media (Twitter, Facebook) to identify future happenings of civil unrest. Through these studies we illustrate the selective superiorities of different sources for specific countries.

3. Unlike many studies of retrospective forecasting of protests, we assess the lead time from when the forecast is made to the actual event date, to assess the forecasting prowess of our approach. Our results demonstrate that we are able to capture significant societal unrest in the above countries with an average lead time of 4.08 days. This illustrates that the approach here can be used in a practical protest forecasting system.

Chapter 2

Related Work

Four categories of related work are briefly discussed here.

2.1 Event detection via text extractions

is an extensively studied topic in the literature. Document clustering techniques are used in [8, 9, 10] to identify events retrospectively or as the stories arrive. Works like [11, 12, 13] focus on extraction patterns (templates) to extract information from text. Ritter et al. [14] show that it is possible to accurately extract a calendar of significant events from Twitter by training a tagger for recognizing event phrases. Highly specialized applications also exist; e.g., Sakaki et al. [15] mine tweets to enable prompt detection of occurences of earthquakes.

Table 2.1: Comparison of our approach against other future retrieval techniques.

	Relative date resolution	Ingest multiple sources?	Reasoning about location	Learning word/phrase filters
'Future' Search Engines [1, 2, 3]	✓			
Time-to-Event Recognition [4, 5]	✓			
Planned Protest Detection [6, 7]		✓		
This paper	✓	✓	✓	✓

2.2 Temporal information extraction

Temporal Information Extraction is another well studied topic. The TempEval challenge [16] led to a significant amount of algorithmic development for temporal NLP. For instance, a specification language for temporal and event expressions in natural language text is described in [17]. Refs. [18] and [19] provide methods to resolve temporal expressions in text (our own work here uses the TIMEN package [18]).

2.3 Event forecasting

Event forecasting is a burgeoning area. Radinsky and Horvitz [20] find event sequences from a corpora and then use these sequences to determine if an event of interest (e.g., a disease outbreak, or a riot) will occur sometime in the future. This work predicts only if a potential event will happen given a historical event sequence but does not geolocate the event to a city-level resolution, as we do here. Kallus [21] makes use of event data from RecordedFuture [22] to determine if a significant protest event will occur in the subsequent three days and casts this as a classification problem. This work only focuses on prediction of significant events (suitably defined) and the forecast is limited to the next three days. Ramakrishnan et al. [23] describe the EMBERS system for forecasting civil unrest using open source indicators but this work is primarily focused on shallow mining of a broad set of data sourceas in contrast to the focused analysis of planned protest announcements that we study here.

Finally, the area of research most closely related to our work is the emerging topic of

2.4 Future Retrieval

. Baeza-Yates [3] providing one of the earliest discussions of this topic; here future temporal information in text is found and used to retrieve content

from search queries that combine both text and time with a simple ranking scheme. Kawai et al. [1] present a search engine (ChronoSeeker) for searching future and past events. They make use of an SVM classifier to disambiguate between the various temporal expressions in a document. Dias et al. [24] classify web snippets into three classes depending on if a future date can/cannot be predicted from the snippet or if it is a rumor. RecordedFuture [22], introduced earlier, conducts real-time analysis of news and tweets to identify mentions of events along with associated times. Anectodally it is estimated that approximately (only) 5–7% of events extracted by RecordedFuture are about the future. Tops et al. [4] aim to classify a tweet talking about an event into discrete time segments and thereby predict the 'time to event'. Bosch et al. [5] use regression techniques to identify the time to an event referred to by a tweet. Jatowt et al. [2] provide a collective image of the future associated with an entity summarizing all future related information available. Becker et al. [25] try to identify more content about known planned events (e.g., a concert) across social media. This work for instance assumes that we know the event beforehand and aims to identify relevant details of the event.

In particular, two publications—Compton et al. [7] and Xu et al. [6]—align very closely to our own work as their emphasis is on protest forecasting. Both works are aimed at forecasting protests but emphasize different data sources and different methodologies. For instance, the work in [7] filters the Twitter stream for keywords of interest and searches for future date mentions in only absolute terms, i.e., explicit mentions of a month name and a number (date) less than 31. Such an approach will not be capable of extracting the more common way in which future dates are referenced, e.g., phrases like "tomorrow," "next tuesday." The work in [6] by the same group of authors uses the Tumblr feed with a smaller set of keywords but again is restricted to the use of absolute time identifiers.

In surveying the state-of-the-art, we arrived at desiderata for a planned protest forecasting system. As shown in Table 2.1, we desire a system that is capable of: i) ingesting a broad range of data sources from both popular news and social media, ii) learning relevant phrases for tracking protests, iii) handling relative mentions of dates, and iv) providing a rich representational

and reasoning basis for location. As Table 2.1 summarizes, current systems provide only partial solutions and the proposed approach addresses all four desired criteria.

Chapter 3

Preliminaries

Our emphasis in this paper is on Latin America. Protest is an important topic of study in this region, as many countries here are democracies struggling to consolidate themselves. The combination of weak channels of communication between citizen and government, and a citizenry that still has not grasped the desirability of elections as the means to affect politics means that public protest will be an especially attractive option. To illustrate the power of protest in Latin America we need only recall that between 1985 and 2011, 17 presidents resigned or were impeached under pressure from demonstrations, usually violent, in the streets. Protests have also resulted in the rollback of price increases for public services, such as during the 'Brazilian Spring' of June 2013. Our goal is to identify calls for protests, strikes, or civil disobedience movements from news, blogs, Tweets, and Facebook pages, with a view toward predicting the **when** (date of the event) and **where**, i.e., event loca-

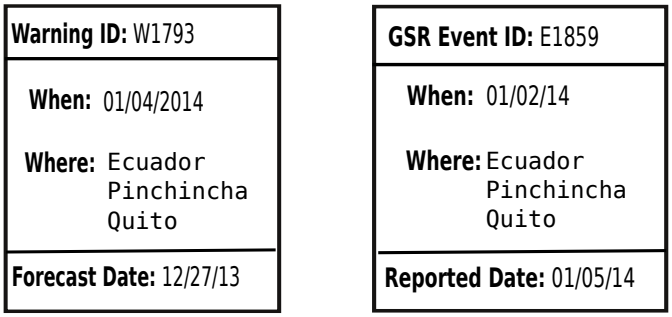

Figure 3.1: An example warning (left) and GSR event (right).

tion, up to city-level resolution, e.g., the city of *Tegucigalpa* in the state of *Francisco Morazan* in the country of *Honduras*). We refer to our forecasts as alerts or warnings (see Fig. 3.1 (left)). In looking at the structure of the alert, it is important to distinguish between the forecast date (when the forecast is made) and the predicted event date (i.e., the **when** of the event).

To evaluate our alerts we have access to a database of protests organized by a third party (source and reference not provided due to double blind reviewing considerations, but will be added later). We refer to this database as the GSR (for Gold Standard Report). Human analysts scan newspapers of record in the countries of interest and catalog protests. The structure of a GSR event (see Fig. 3.1 (right)) is similar to that of an alert with the only difference being that an event record captures both the reported date (i.e., the date of newspaper publication) and the event date (i.e., when the newspaper article reports the protest as having happened). The GSR is available from Nov 2012 and is used in this paper primarily to help evaluate the performance of our system. A manual examination of GSR (as mentioned in Section 1) revealed that over 75% of the protests were organized and had clear triggering circumstances with political entrepreneurs leading the charge to protest.

Chapter 4

Probabilistic Soft Logic

In this section, we briefly describe probabilistic soft logic (PSL) [26], a key component of our geocoding strategy described later. PSL is a framework for collective probabilistic reasoning on relational domains. PSL models have been developed in various domains, including collective classification [27], ontology alignment [28], personalized medicine [29], opinion diffusion [30] , trust in social networks [31], and graph summarization [32]. PSL represents the domain of interest as logical atoms. It uses first order logic rules to capture the dependency structure of the domain, based on which it builds a joint probabilistic model over all atoms. Instead of hard truth values of 0 (false) and 1 (true), PSL uses soft truth values relaxing the truth vlaues to the interval $[0, 1]$. The logical connectives are adapted accordingly. This makes it easy to incorporate similarity or distance functions.

User defined *predicates* are used to encode the relationships and attributes and *rules* capture the dependencies and constraints. Each rule's antecedent is a conjunction of atoms and its consequent is a dis-junction. The rules can also labeled with non negative weights which are used during the inference process. The set of predicates and weighted rules thus make up a PSL program where known truth values of ground atoms derived from observed data and unknown truth values for the remaining atoms are learned using the PSL inference.

Given a set of atoms $\ell = \{\ell_1, \ldots, \ell_n\}$, an interpretation defined as $I : \ell \rightarrow [0, 1]^n$ is a mapping from atoms to soft truth values. PSL defines a probability distribution over all such interpretaions such that those that satisfy more

ground rules are more probable. *Lukasiewicz t-norm* and its corresponding co-norm are used for defining relaxations of the logical AND and OR respectively to determine the degree to which a ground rule is satisfied. Given an interpretation I, PSL defines the formulas for the relaxation of the logical conjunction ($\wedge$), disjunction ($\vee$), and negation ($\neg$) as follows:

$$\begin{aligned}\ell_1 \tilde{\wedge} \ell_2 &= \max\{0, I(\ell_1) + I(\ell_2) - 1\},\\ \ell_1 \tilde{\vee} \ell_2 &= \min\{I(\ell_1) + I(\ell_2), 1\},\\ \tilde{\neg} l_1 &= 1 - I(\ell_1),\end{aligned}$$

The interpretation I determines whether the rules is satisfied, if not, the *distance to satisfaction*. A rule $r \equiv r_{body} \rightarrow r_{head}$ is satisfied if and only if the truth value of head is at least that of the body. The rule's distance to satisfaction measures the degree to which this condition is violated.

$$d_r(I) = \max\{0, I(r_{body}) - I(r_{head})\}$$

PSL then induces a probability distribution over possible interpretations I over the given set of ground atoms l in the domain. If R is the set of all ground rules that are instances of a rule from the system and uses only the atoms in I then, the probability density function f over I is defined as

$$f(I) = \frac{1}{Z}\exp[-\sum_{r\in R}\lambda_r(d_r(I))^p] \tag{4.1}$$

$$Z = \int_I \exp[-\sum_{r\in R}\lambda_r(d_r(I))^p] \tag{4.2}$$

where λ_r is the weight of the rule r, Z is the continuous version of the normalization constant used in discrete Markov random fields, and $p \in \{1, 2\}$ provides a choice between two different loss functions, linear and quadratic. The values of the atoms can be further restricted by providing linear equality and inequality constraints allowing one to encode functional constraints from the domain.

PSL provides for two kinds of inferences: (a) most probable explanation and (b) calculation of the marginal distributions. In the MPE inference given a partial interpretation with grounded atoms based on observed evidence, the PSL program infers the truth values for the unobserved atoms satisfying the most likely interpretation. In the second setting, given ground truth data for all atoms we can learn the weights for the rules in our PSL program.

Chapter 5

Approach

The general approach we adopt is to identify open-source documents that appear to indicate civil unrest event planning, extract relevant information from identified documents and use that as the basis for a structured warning about the planned event (see Fig. 5.1). We ingest a wide array of textual documents, including RSS feeds (news and blogs), mailing lists, URLs referenced in tweets, the contents of the tweets themselves, and Facebook event pages. All harvested documents are subjected to linguistic analysis; candidate documents are identified using a list of (learnt) phrases associated with protest event planning; date and location information is extracted from the text and reasoned about to generate a warning. Location information is standardized to conform to a standard (in our case, we use the World Gazeteer). Each of

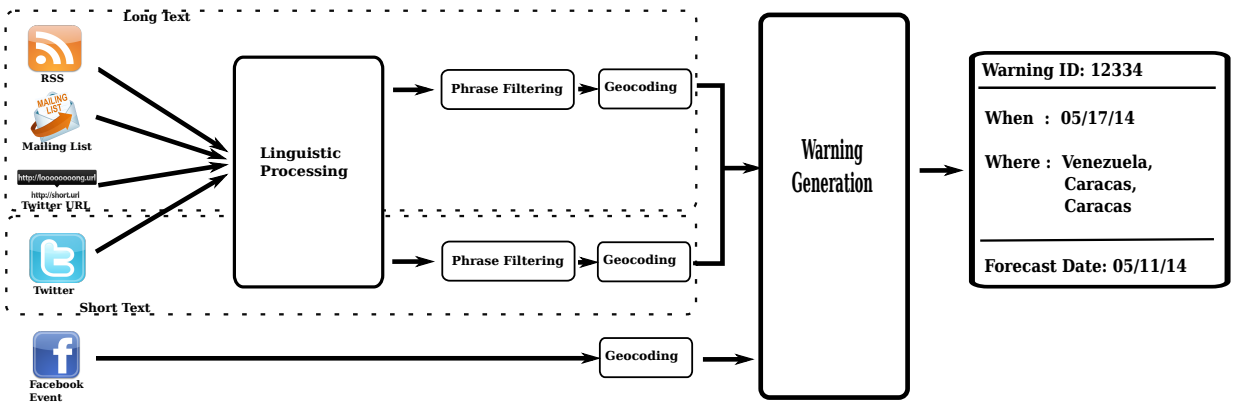

Figure 5.1: Schematic of the planned protest detector that ingests five different types of data sources.

these processing steps (see Fig. 5.1) is outlined next.

5.1 Linguistic Preprocessing

All textual input (e.g., tweets, news articles, blog postings) is subjected to shallow linguistic processing prior to analysis. This involves identifying the language of the document, distinguishing the words (tokenization), normalizing words for inflection (lemmatization), and identifying expressions referring to people, places, dates and other entities and classifying them (named entity extraction). Since our region of interest is Latin America, the collection of text harvested is inherently multilingual, with Spanish, Portugese, and English as the dominating languages; we use Basis Technology's Rosette Linguistics Platform (RLP) suite of multilingual commercial tools (`http://www.basistech.com/text-analytics/rosette/`) for this stage. The output of linguistic preprocessing serves as input to subsequent deeper analysis in which date expressions are normalized and the geographic focus of the text identified.

Date processing is particularly crucial to the identification of future oriented statements. We use the TIMEN [18] date normalization package to normalize and deindex expressions referring to days in English, Spanish and Portuguese. This system makes use of meta-data such as the day of publication, and other information about the linguistic context of the date expression to determine for each date expression, what day (or week, month or year) it refers to. For example in a tweet produced on June 10, 2014, the occurrence of the term *Friday* used in a future-tense sentence *We'll get together on Friday* will be interpreted as June 13, 2014. Each expression identified as a date by the RLP preprocessor is normalized in this way.

5.2 Phrase filtering

In order to identify relevant documents, input documents are filtered on a set of key phrases, i.e., the text of the document is searched for the presence of

one or more key phrases in a list of phrases which are indicative of an article's focus being a planned civil unrest event. The list of key phrases indicating civil unrest planning was obtained in a semi-automatic manner, as detailed in Section 5.2.2. Articles which do match are processed further, those that do not are ignored.

5.2.1 Phrase matching

Our key phrase matching is highly general and linguistically sophisticated. The phrases in our list are general rules for matching, rather than literal string sequences. Typically a phrase specification comprises: two or more word lemmas, a language specification, and a separation threshold. This indicates that words—potentially inflected forms—in a given sequence potentially separated by one or more other words, should be taken to be a match. We determined that this kind of multi-word key phrases was more accurate than simple keywords for extracting events of interest from the data stream.

The presence of a keyphrase is checked by searching for the presence of individual lemmas of the keyphrase within the same sentence separated by at most a number of words that is fewer than the separation threshold. This method allows for linguistically sophisticated and flexible matching, so, for example, the keyphrase [***plan protest*, 4, English**] would match the sentence *The students are planning a couple big protests tomorrow* in an input document.

5.2.2 Phrase list development

The set of key phrases was tailored (slightly) to the genre of the input. In particular different phrases were used to identify relevant news articles and blogs from those used to filter Tweets. The lists themselves were generated semi-automatically.

Initially, a few seed phrases were obtained manually with the help of subject matter experts. An analysis of news reports for planned protests in the print

media helped create a minimum set of words to use in the query. We choose four nouns from the basic query that is used predominantly to indicate a civil unrest in the print media - *demonstration, march, protest* and *strike*. We translated them into Spanish and Portuguese, including synonyms. We then combined these with future-oriented verbs, e.g., *to organize*, *to prepare*, *to plan*, and *to announce*. For twitter, shorter phrases were identified, and these had a more direct call for action, e.g., *marchar*, *manhã de mobilização*, *vamos protestar*, *huelga*.

To generalize this set of phrases, the phrases were then parsed using a dependency parser [33] and the grammatical relationship between the core nominal focus word (e.g., *protest*, *manifestación*, *huelga*) and any accompanying word (e.g., *plan*, *call*, *anunciar*) was extracted. These grammatical relations were used as extraction patterns as in [13] to learn more phrases from a corpora of sentences extracted from the data stream of interest (either news/blogs or tweets). This corpus consists of sentences that contained any one of the nominal focus words and also had mentions of a future date. The separation threshold for a phrase was also learned, being set to the average number of words separating the nominal focus and the accompanying word.

The set of learned phrases is then reviewed by a subject matter expert for quality contraol. Using this approach, we learned 112 phrases for news articles and blogs and 156 for tweets. This phrase learning process is illustrated in Fig. 5.2.

5.3 Geocoding

After linguistic preprocessing and suitable phrase filtering, messages are geocoded with a specification of the geographical focus of the text—specified as a city, state, country triple—that indicates the locality that the text is about. We make use of different geocoding methodologies for Twitter messages, for Facebook Events pages, and for news articles and blogs. These are described below.

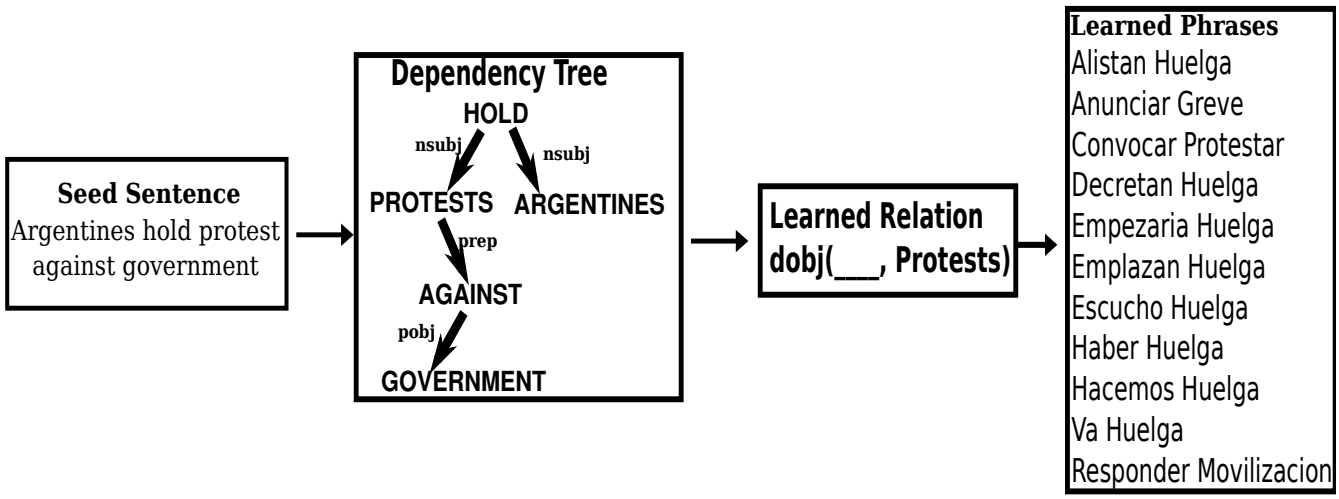

Figure 5.2: An example of phrase learning for detecting planned protests.

5.3.1 Twitter

For tweets, the geo-focus of the message is generated by a fairly simple set of heuristics. In particular, Twitter geocoding is achieved by first considering the most reliable but least available source, the geotag (latitude, longitude) of the tweet itself (this is available for about 10% of our sample from Twitter). This provide an exact geographic location that can be reverse geocoded into a place name and used as the geo-focus. We find the nearest geo-coded point in our extended gazetteer (using a kd-tree data structure) for this purpose. If the tweet is not geocoded, we consider Twitter *places* metadata and use place names present in these metadata fields to geocode the place names into geographical coordinates. Finally, if none of this is available, we consider the text fields contained in the user profile (location, description) as well as the tweet text itself to find mentions of relevant locations. Additional toponym disambiguiation heuristics are used to identify the actual referent of the mention.

5.3.2 Facebook

Similar methods are used to geocode event data extracted from Facebook event pages. Since only Facebook events that have a venue are used and

since the venue of a Facebook event generally specifies a latitude, longitude, and physical address information, identifying the location is a fairly trivial task. In cases where only latitude and longitude are given, we apply reverse-geocoding mechanisms similar to those used for Twitter.

5.3.3 News and Blogs

For longer articles such as news articles, the geo-focus of the message is identified using much more complex methods To extract the protest location from news articles, we use PSL to build probabilistic models that infer the intended location of a protest by weighing evidence coming from the Basis entity extractions and information in the World Gazeteer.

The primary rules in the model encode the effect that Basis-extracted location strings that match to gazatteer aliases are indicators of the article's location, whether they be country, state, or city aliases. Each of these implications is conjuncted with an prior for ambiguous, overloaded aliases that is proportional to the population of the gazetteer location. For example, if the string "Los Angeles" appears in the article, it could refer to either Los Angeles, California, or Los Ángeles in Argentina or Chile. Given no other information, our model would infer a higher truth value for the article referring to Los Angeles, California, because it has a much higher population than the other options.

$$ENTITY(L, location) \tilde{\wedge} REFERSTO(L, locID) \rightarrow PSLLOCATION(Article, locID)$$

$$ENTITY(C, location) \tilde{\wedge} IsCountry(C) \rightarrow ArticleCountry(Article, C)$$

$$ENTITY(S, location) \tilde{\wedge} IsState(S) \rightarrow ArticleState(Article, S)$$

(Note that the above are not deterministic rules; e.g., they do not use the logical conjunction $\wedge$ but rather the Lukasiewicz t-norm based relaxation $\tilde{\wedge}$. Further, these rules do not fire deterministically but are instead simultaneously solved for satisfying assignments as described in Section 4.)

The secondary rules, which are given half the weight of the primary rules, perform the same mapping of extracted strings to gazetteer aliases, but for extracted persons and organizations. Strings describing persons and organizations often include location clues (e.g., "mayor of Buenos Aires"), but intuition suggests the correlation between the article's location and these clues may be lower than with location strings.

$$ENTITY(O, organization) \,\tilde{\wedge}\, REFERSTO(O, locID) \rightarrow PSLLOCATION(Article, locID)$$

$$ENTITY(O, organization) \,\tilde{\wedge}\, IsCountry(O) \rightarrow ArticleCountry(Article, O)$$

$$ENTITY(O, organization) \,\tilde{\wedge}\, IsState(O) \rightarrow ArticleState(Article, O)$$

Finally, the model includes rules and constraints to require consistency between the different levels of geolocation, making the model place higher probability on states with its city contained in its state, which is contained in its country. As a post-processing step, we enforce this consistency explicitly by using the inferred city and its enclosing state and country, but adding these rules into the model makes the probabilistic inference prefer consistent predictions, enabling it to combine evidence at all levels. As an example of how PSL aids in location identification, the example from Fig. 1.1 is revisited in Fig. 5.3.

$$PSLLOCATION(Article, locID) \,\tilde{\wedge}\, Country(locID, C) \rightarrow ArticleCountry(Article, C)$$

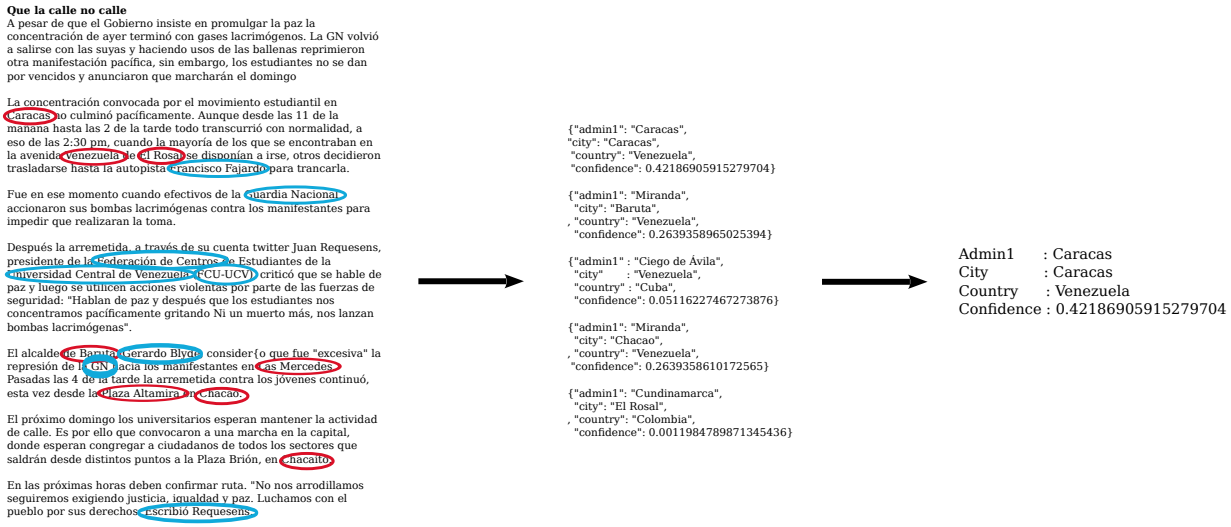

Figure 5.3: An example of location inference using PSL. Red circles denote named entities identified as locations and blue denotes other types of entities. The article describes students planning a march on Sunday. It identifies multiple locations, e.g., Chacao, El Roso, and the Francisco Fajardo highway where protests have been happening. There is also a reference to a quote by the mayor of Baruto. Mentions of such multiple locations are resolved using our PSL program to the intended location, here Caracas.

$$PSLLOCATION(Article, locID) \tilde{\wedge} Admin1(locID, S) \rightarrow ArticleState(Article, S)$$

5.3.4 Warning Generation

After being subject to the preprocessing steps, above, all documents that are identified as containing a key phrase are further filtered by searching for the presence a future date in the passage containing the key phrase and for the existence of an identified geographical focus for the text. Documents that meet all these critera are used as the basis for a warning about a planned civil unrest event (Twitter postings are only used as the basis for a warning if the tweet is re-tweeted at least five times). A warning is generated for the date indicated by the future date expression and the location which is the geographical focus of the document. In the case of Facebook, an event page is considered to be good evidence for an alert if there are more attendees for the event than rejects. The date and location are read off from the event

page directly.

Chapter 6

Experiments

We evaluate our planned protest detection system using metrics similar to those described by Ramakrishnan et al. [23] in evaluating their work. Given a set of alerts issued by the system and the GSR comprising actual protest incidents, we aim to identify a correspondence between the two sets via a bipartite matching. An alert can be matched to a GSR event only if i) they are both issued for the same country, ii) the alert's predicted location and the event's reported location are within 300km of each other (the distance offset), and iii) the forecasted event date is within a given interval of the true event date (the date offset). Once these inclusion criteria apply, the quality score (QS) of the match is defined as a combination of the location score (LS) and date score (DS):

$$\text{QS} = (LS + DS) * 2 \tag{6.1}$$

where

$$\text{LS} = 1 - \frac{\min(\text{distance offset}, 300)}{300} \tag{6.2}$$

and

$$\text{DS} = 1 - \frac{\min(\text{date offset}, \text{INTERVAL})}{\text{INTERVAL}} \tag{6.3}$$

Here, we explore INTERVAL values from 0 to 7. if an alert (conversely, GSR event) cannot be matched to any GSR event (alert, respectively), these unmatched alerts (and events) will negatively impact the precision (and recall) of the system. The lead time, for a matched alert-event pair, is calculated as the difference between the date on which the forecast was made and the

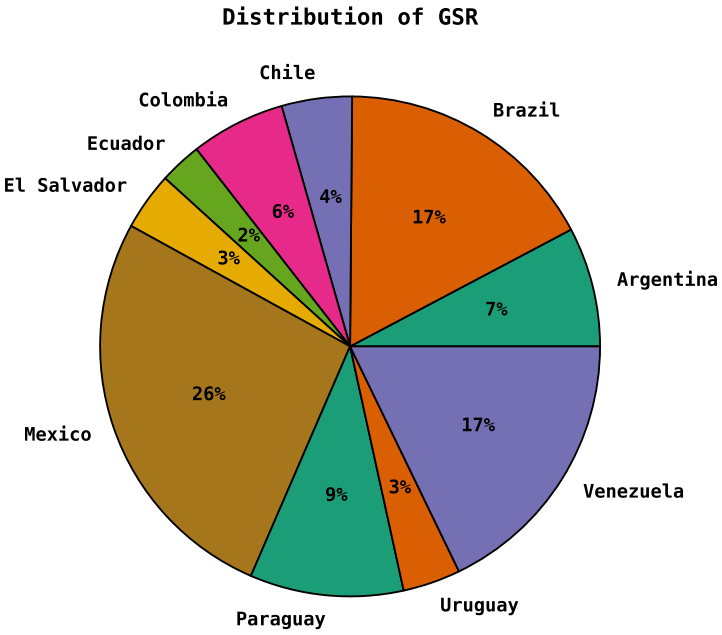
date on which the event was reported (this should not be confused with the date score, which is the difference between the predicted event date and the actual event date). Lead time concerns itself with reporting and forecasting, whereas the date score is concerned with quality or accuracy.

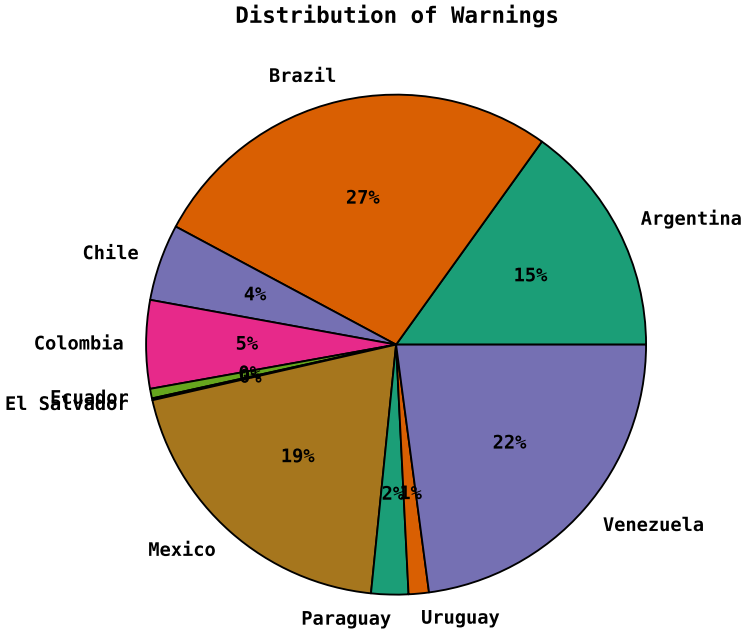
We conduct a series of experiments to evaluate the performance of our system.

Distribution of protests detected by the system compared with the actual distribution of protests in the GSR? Fig. 6.1 reveals pie charts of both distributions. As shown, Mexico, Brazil, and Venezuela experience the lion's share of protests in our region of interest, and the protests detected also match these modes although not the specific percentages. The smaller countries like Ecuador, El Salvador, and Uruguay do experience protests but which are not as prominently detected as those for other countries; we attribute this to their smaller social media footprint (relative to countries like Brazil and Venezuela).

Are there country-specific selective superiorities for the different data sources considered here? Table 6.1 presents a breakdown of perfomance, country-wise and source-wise, of our approach for a recent month, viz. March 2014. It is clear that the multiple data sources are necessary to achieve a high recall and that by and large these sources are providing mutually exclusive alerts. (Note also that some data sources do not produce alerts for specific countries.) Between Twitter and Facebook, the former is a better source of alerts for countries like Chile and the latter is a better



(a) GSR distribution from 2012-11 to 2014-03.



(b) Alerts distribution from 2012-11 to 2014-03.

Figure 6.1: Distribution of alerts and GSR events across the countries studied in this paper.

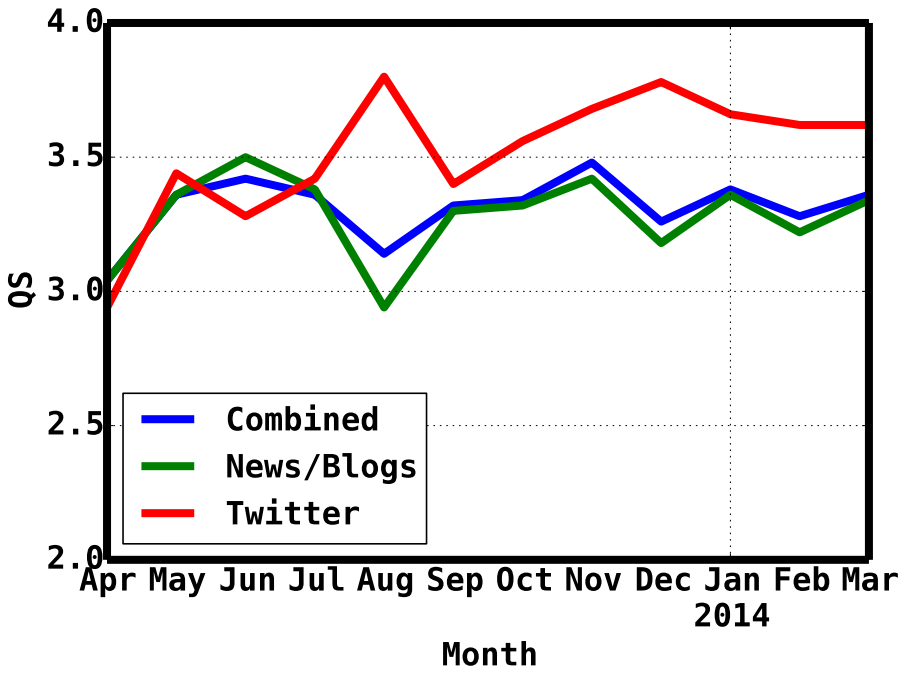


Figure 6.2: Quality Score over the months

source for Argentina, Brazil, Colombia, and Mexico. News and blogs achieve higher recall than social media sources indicating that most plans for protests are announced in established media. They are also higher quality sources for alerts in countries like El Salvador, Paraguay, and Uruguay. Finally, note that news and blogs offer a much higher lead time (4.57 days) as compared to that for Facebook (2.44 days) or for Twitter (2.82 days). The quality scores are further broken down in Table 6.2 into their date and location components. A longitudunal perspective on quality scores is given in Fig. 6.2. Note that in general Twitter tends to have a higher quality score as multiple re-tweets of future event mentions is a direct indicator of the popularity of an event as well as the intent of people to join an event. In contrast, mentions of future events in news do not directly shed any insight into popularity or people's support for the event's causes.

How did our system fare in detecting key country-wide protests? The recent Venezuelan protests against President Nicolas Maduro and the Brazilian Protests during June 2013 against bus fare hike were two signifi-

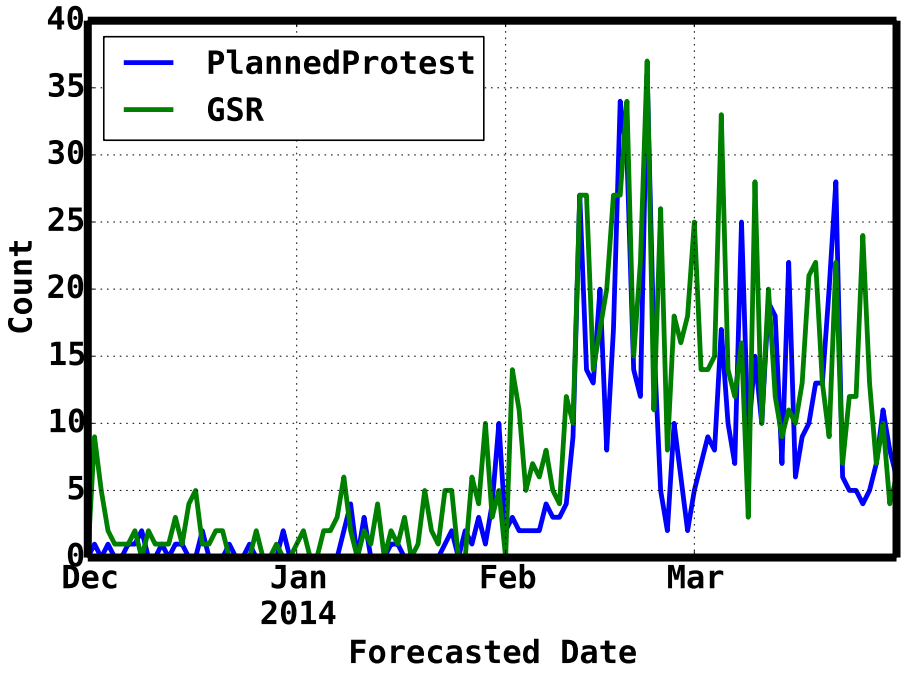

Figure 6.3: Venezuelan Protests

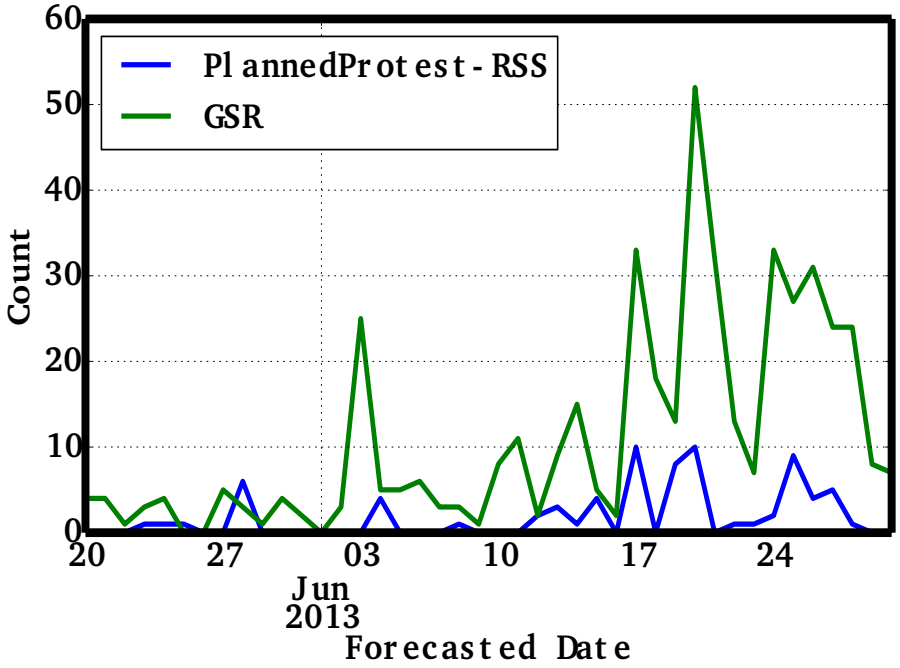

Figure 6.4: System Performance during Brazilian Spring

cant protests during our period of evaluation. Fig. 6.3 and Fig. 6.4 describe our performance under these two situations illustrating the count of protests detected against the GSR. Notice that our system was able to identify the Venezuelan protests much better than the Brazilian protests. This is because there was a significant amount of spontaineity to the Brazilian protests; they arose as discontent about bus fare increases but later morphed into a broader set of protests against government and most of these subsequent protests were not planned.

What is the tradeoff between lead time and quality? Fig. 6.5 shows that the QS of the planned protest model decreases (as expected) with lead time, initially, but later rises again. The higher quality scores toward the right of Fig. 6.5 are primarily due to Facebook event pages.

How does the method perform under stringent matching criteria? Fig. 6.6 shows the perfomance of the model when the matching window is

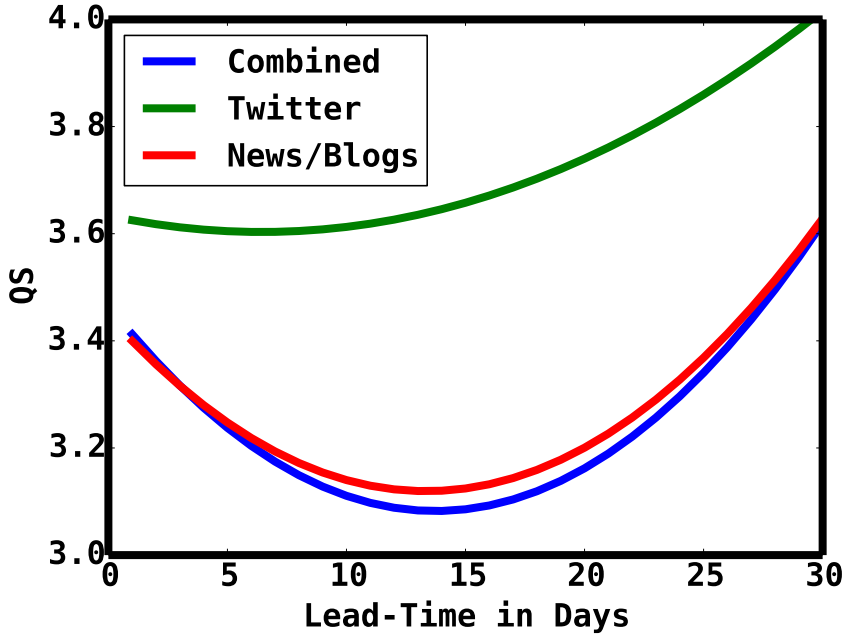

Figure 6.5: Lead-Time vs Quality Score

varied from 7 to 1 in steps. We can see that the performance degrades quite gracefully even under the strict matching interval of a 1-day difference.

What is the distribution of quality scores? The clear mode toward the right side of the Fig. 6.7 signifies that a majority of the planned protest alerts are of high quality. Further, the quality score distribution is unimodal suggesting that the careful reasoning of locations and date normalization are crucial to achieving high quality.

Chapter 7

Discussion

We have described an approach to forecasting protests by detecting mentions of future events in news and social media. The two twin issues of i) resolving the date and ii) resolving the location have been addressed satisfactorily to realize an effective protest forecasting system. As different forms of communication media gain usage, systems like ours will be crucial to understanding the concerns of citizenry.

Our future work is aimed at three aspects. First, to address situations such as nationwide protests and systems of protests, we must generalize our system from generating protests at a single article level to digesting groups of articles. This will require more sophisticated reasoning using PSL programs. Second, we would like to generalize our approach that currently does detection of overt plans for protest to not-so-explicitly stated expressions of discontent. Finally, we plan to consider other population-level events of interest than just civil unrest, e.g., domestic political crises, and design detectors to recognize the imminence of such events.
